## TITTEL

### MOSJØEN ALUMINIUMVERK

ICE AND SNOW ACCRETION ON PIPE CONVEYOR

## UTARBEIDET AV

SVEIN M. FIKKE

## OPPDRAUGSGIVER

MOSAL ALUMINIUM  
MOSJØEN ALUMINIUMVERK  
OPPDRAUGSNR. 134 789/3810 2030

## SAMMENDRAG

19 years of temperature and precipitation records from the weather stations Mosjøen - Mosal and Vardefjell are investigated with respect to the probability for supercooled precipitation and snow accretion. Significant amounts of supercooled precipitation have not occurred during the investigated period. Wet snow may occur on the average 1 - 2 times per year with precipitation rates of 5 - 10 mm/12 hours in 2/3 of the cases. The lowest measured air temperature is -31.4°C.

MOSJØEN ALUMINIUMVERK  
ICE AND SNOW ACCRETION ON PIPE CONVEYOR

## 1. INTRODUCTION

In a letter dated 1 August 1986 (appendix 1) The Norwegian Meteorological Institute (DNMI) was asked to evaluate the dimensioning wind speeds for a pipe conveyor for aluminiumoxide from the harbour to the top of the siloes. Under a meeting in Oslo 4 August 1986 it was concluded that an already performed wind analysis for Mosjøen (1) was sufficient. However, the question of snow and ice shedding from the up to 45 m high lattice suspension and down on the trafficated areas underneath was raised.

An investigation of the probabilities for ice and snow accretion was ordered as a co-project between DNMI and the Norwegian Research Institute of Electricity Supply A/S (EFI) (appendix 2). EFI has employed a meteorologist who is attached to DNMI in order to work with wind and ice loadings on e.g. transmitting towers and electrical transmission lines.

The analyses in this report are based on existing computer programs available at DNMI.

## 2. SHORT DESCRIPTION OF THE SYSTEM

The pipe conveyor is in principle similar to a conventional conveyor belt, except that the belt is formed into a cylindric pipe between the end stations. The return pipe is located just underneath and the whole system is suspended by a lattice-work construction. The conveyor system is about 830 m long and rises from about 6 m above ground in the harbour area to about 45 m above ground over the roofs of the furnace halls. The pipe conveyor and the catwalks will be enclosed by a steel pipe on the about 270 m long part above the furnace halls in order to ensure safe access in bad weather. The steel pipe has a diameter of 2.7 m and is suspended with a V-shaped lattice construction underneath.

The heating of the lattice construction and the steel pipe from the pipe conveyor is considered to be negligible.

## 3. PRECIPITATION ICE

### 3.1 Processes

Precipitation ice is a notation for ice accretion formed together with precipitation, either as glaze formed by supercooled rain or as wet snow.

#### 3.1.1 Supercooled rain

Supercooled rain preassumes a so-called "temperature inversion", i.e. a temperature increase with height. Near the ground there must be sub-freezing temperatures and a warm, melting layer aloft. Falling snow crystals from above will then melt into raindrops in the melting layer and become supercooled in the freezing layer below. These drops will freeze immediately when hitting the

surface or objects in the air stream.

### 3.1.2 Snow accretion

Snow accretion can be formed in two ways, either as for supercooled rain if the melting layer is shallow and melts the snow crystals only partially, or if the surface air temperature is slightly above 0°C. In the last and most common case the partly melted snow crystals will adhere to objects in the air stream due to the free water in the crystals. If the wind speed is moderate to strong (say above 10 m/s) considerable layers of wet and heavy layers may accrete on e.g. lattice constructions. If the temperature later on drops, this layer may of course freeze and remain on the construction until the temperature again rises above freezing.

## 3.2 Methods

We have neither satisfying theoretical methods nor a necessary time resolution in the meteorological data to identify cases and quantify amounts of accreted ice from precipitation. We are therefore confined to qualitative methods and evaluation. The outlines of the evaluations will be the following:

Supercooled rain preassumes, as stated above, a melting layer aloft in the atmosphere. This could naturally be the case in Mosjøen which is situated in a relatively narrow valley. If a warm front with precipitation comes in from the sea after a period with cold weather, the cold and stable air may still remain in the lower part of the valley and form the freezing layer necessary for supercooled rain.

Hence, we must examine the frequency of such temperature inversions together with precipitation.

Wet snow accretion is connected with a small temperature range of probably the order 0.5 - 1°C above the freezing point. As the time resolution in our data is 6 hours, we have no possibilities to examine the precipitation rate within this range. We are limited to examine the precipitation rates in a much larger temperature interval.

A special attention is paid to the extreme precipitation amounts in the winter season.

## 3.3 Weather stations and data records

The weather station Mosjøen-Mosal has been in operation more or less continuously since 1958, but is now closed down. This station has continuous and complete data in DNMIs data-base for the period 1965-1983, and this 19 years period is therefore chosen for the present analyses.

A nearby station, Vardefjell, 634 masl. approx. 5 km NE of Mosjøen, is very suitable for identifying cases of temperature inversions. The period 1965-83 is also covered by Vardefjell.

## 3.4 Extreme precipitation rates and temperature

Table 1 shows the 10 highest daily precipitation amounts for each of the 12 months and the year. During the months October to April 60 mm or more is measured for one day (24 hours) 13 times, and the absolute maximum of 160.5 mm was measured on 20 March 1966.

An examination of the temperature-observations shows that in most of these cases the precipitation was strictly rain with temperatures of 5-8°C. Some outprints of the records are shown in table 2. (Note that the precipitation amounts in table 1 is the total amount for the period 07-07 hours.) In 3 of the 13 cases

there was a significant rise from sub-zero to above zero temperatures during the event, and an eventual wet snow acceration must have been of very short duration. See table A for 7 - 8 January 1971, 10 - 11 March 1965 and 22 - 23 March 1973.

Hence we may conclude that the extreme precipitation amounts during the winter season in Mosjøen is limited either to rain alone, or with a transition from snow to rain with a relative short period with mixed precipitation. Hence eventual cold air in the valley must either be drained out quickly or warmed by the rain in such cases.

### 3.5 Precipitation and temperature inversions

A complete analysis of temperature-inversions should include an examination of the vertical structure of the atmosphere measured at our radiosonde station at Bodø. (Vertical profiles of temperature, humidity and wind are measured twice a day by means of balloons and radio transmitters.) However, at present it is rather time consuming to combine these data with the surface data, it would for instance be necessary with special programming. As we already have the nearby station Vardefjell in a suitable height, this work was found not worthwhile.

We have already found that no significant inversion cases are connected with the extreme precipitation rates in winter. Due to the amount of data a different method is used for the moderate to small precipitation rates.

The computer program "KOMB" identifies cases where selected weather parameters are within separate limits for each of 2 or more weather stations at the same hour. In this case, the significant inversion cases should be found when the temperature criteria listed in table 3 are fulfilled for the same observation hour.

Table 3. Temperature criteria used for inversion analysis

	Mosjøen-Mosal		Vardefjell	
	Min.	Max.	Min.	Max.
Temperature at the obs. hour	-10	2	-10	10
Min. temp. for the past 12 hours	-30	-2	-10	2
Max. temp. for the past 12 hours	-10	2	0	10

The temperature criteria are defined very wide in order to let all "suspect" cases be included. Additionally, only 12 hour periods with 2 mm precipitation or more at Mosjøen-Mosal were chosen. Since 1965 only 4 cases were found, and one of these, 22 March 1973, is already discussed in section 3.4.

A further examination of the 3 remaining cases revealed that in only one case on 19 December 1967 there was definitely a melting layer aloft. At 19 hr there was measured 2.9 mm precipitation and only a part of this came as supercooled rain.

Another case, 11 December 1975, did most probably not include a melting layer as the maximum temperature at Vardefjell was only  $0.1^{\circ}\text{C}$  during the actual precipitation period. The corresponding maximum temperature in Mosjøen was  $-1.4$  and the precipitation height for 12 hours was 21.5 mm.

We may then conclude that significant amounts of supercooled precipitation have not occurred in Mosjøen during the examined period.

### 3.6 Precipitation rates near 0°C

As stated earlier we have no possibility to identify exactly the cases when wet snow accretion occurs. This phenomenon is probably very sensitive to the course of the precipitation rate and temperature, but the exact connections are not established theoretically. We assume that the accretion rate is somewhat proportional to the precipitation rate. A qualitative evaluation of the probability of the accreted wet snow can therefore be given from the distribution of precipitation rates around 0°C.

The observations from Mosjøen-Mosal have been sorted as follows:

All cases with precipitation rates of 5 mm or more within the temperature range of -5 to +5°C are counted. Altogether 539 cases were found for the period 06.1964 - 12.1983. The precipitation rates are distributed as shown in table 4.

Table 4. Distribution of precipitation rates  
25mm/12 hours between -5 and +5°C.

Precip. rate (mm/12 hours)	Number of cases
5 - 10	360
10 - 15	110
15 - 20	44
20 - 25	11
25 - 30	10
30 - 35	2
35 - 40	2 (1 is 22 March 1973)

The number of cases resulting in wet snow accretion is estimated to be less than 10%. This means that the probability of "wet snow" cases are less than 3 per year, or more probably of the order 1-2 per year on the average.

It is also seen from table 4 that 2/3 of the potential cases are with precipitation between 5 and 10 mm and only 5% with more than 20 mm.

### 4. LOW TEMPERATURES

Table 5 shows a distribution of concurrent temperatures and wind forces in Beaufort for the years 1965-83. The values in table 5 represent the state at the observation hours. It should be noted that the lowest temperatures are not connected with calm weather, but with light to gentle breeze (force 2 and 3), or with wind speeds up to about 5 m/s.

The absolute minimum temperature is -31.4°C measured 5 February 1966. In December 1971 the minimum temperature was -31.3°C, as can be seen from the monthly records of averages and extremes in table 6.

### 5. CONCLUSIONS

- The analyses of precipitation and temperature data for the weather stations Mosjøen-Mosal and Vardefjell suggest wet snow accretion of the order 1-2 cases per year on the average. These cases are connected with precipitation rates of 5-10 mm/12 hours in 2/3 of the cases.

- Supercooled rain is not significant.
- Temperatures less than  $-30^{\circ}\text{C}$  must be expected, probably down to  $-35^{\circ}\text{C}$  with a return period of 50 years.

TABLE 2. WEATHER OBSERVATIONS FOR SPECIFIC  
DAYS FROM THE WEATHER STATION  
MOSJØEN - MOSAL

Significant symbols:

DT - Date  
KL - Local hour  
TTTTT - Air temperature (actual)  
TN - Minimum temperature for the last 12 hours  
TX - Maximum temperature for the last 12 hours  
UUU - Relative humidity  
DD - Wind direction in degrees/10  
F - Wind force (Beaufort scale)  
RRRRR - Precipitation amount (mm) for the last 12 hours  
SSS - Snow depth (cm)  
N - Cloud amount (scale 0 - 8)  
VV - Visibility (special code)  
V1-V7 - Symbols for present (V1-V3) and past (V4-V7) weather  
The most important are:  
S - snow SB - snow shower  
R - rain RB - rain shower  
RL - mixed rain/snow LB - rain/snow shower  
SO - sunshine RL - clean air  
BX - Maximum wind force since previous observation

#### RØRTRANSPORTANLEGG FOR ALUMINIUMOKSYD

---

Ved Mosjøen Aluminiumverk ser en nå på mulighetene for å bygge et nytt transportanlegg for aluminiumoksyd fra våre havnesiloer til silo C.

Transportanlegget er av en ny konstruksjon, lukket rørtransport, men som i hovedprinsippet har mye til felles med tradisjonelle transportbånd når det gjelder understøttelse, fagverksoppbygging osv.

På grunn av at avlasting til siloene ved elektrolysehallene må skje på silotopp kreves det temmelig høye understøtteseskonstruksjoner for dette "transportbåndet".

Systemet markedsføres av firmaet "Simmering - Graz-Pauker AG" Wien - norsk agent er Saxlund A/S, Risør v/hr. Markussen.

Vedlagt følger brev fra SGP samt tegninger som viser oppbygningen av det nye transportanlegget som vi vennligst ber Dem vurdere m.h.t. vindbelastninger.

I denne forbindelse refereres det til telefonsamtale med en av Deres medarbeidere 3. juli d.å. Ønsker De ytterligere informasjoner ber jeg Dem vennligst kontakte P. Kjensli, Mosjøen Aluminiumverk eller undertegnede når jeg er tilbake fra ferie i uke 33.

Med hilsen  
Mosjøen Aluminiumverk  
Effektivisering Transport/lager

  
T. F. Sætre
